Abstract

Spherical robots are a format that has not been thoroughly explored for the application of mobile mapping. In contrast to other designs, it provides some unique advantages. Among those is a protective spherical shell that protects internal sensors and actuators from possible harsh environments, as well as an inherent rotation for locomotion that enables measurements in all directions. Mobile mapping always requires a high-precise pose knowledge to obtain consistent and correct environment maps. This is typically done by a combination of external reference sensors such as Global Navigation Satellite System (GNSS) measurements and inertial measurements or by post processing the data and registering the different measurements to each other. In indoor environments, the GNSS reference is not an option. Hence many mobile mapping applications turn to the second option. An advantage of indoor environments is that human-made environments usually have a certain structure, such as parallel and perpendicular planes. We propose a registration procedure that exploits this structure by minimizing the distance of measured points to a corresponding plane. Further, we evaluate the procedure on a simulated dataset of an ideal corridor and on an experimentally acquired dataset with different motion profiles. We show that we nearly reproduce the ground truth for the simulated dataset and improve the average point-to-point distance to a reference scan in the experimental dataset. The presented algorithms are required to work completely autonomously.

Keywords: Mobile Mapping, SLAM, Spherical Robot

2021 MSC: 00-01, 99-00

1. Introduction

Today's robots for mobile mapping come in all shapes and sizes. State of the art for urban environments are laser scanners mounted to cars. Smaller robotic systems are particularly used when cars no longer have access. Examples for this are human operated systems such as Zebedee [1], a small Hokuyo 2D scanner on a spring, VILMA [2], a rolling FARO scanner operating in profiler mode, RADLER [3], a SICK 2D laser scanner mounted to a unicycle, or a backpack mounted "personal laser scanning system" as in [4] or [5]. Recently more and more autonomous systems gained maturity. A stunning example is Boston Dynamics' quadruped "Spot" that autonomously navigates and maps human environments [6]. Also, the mobile mapping approaches implemented on the ANYmal platform such as [7] were very successful. Of all these formats, one has not been explored thoroughly in the scientific community: The spherical mobile mapping robot. Yet this provides some very promising advantages over the other formats. For one, the locomotion of a spherical robot inherently results in rotation. That way, a sensor fixed inside the spherical structure will cover the entire environment, given the

required locomotion without the need for additional actuators for the sensors. This requires a solution for the spherical simultaneous localization and mapping (SLAM) problem given the six degrees of freedom of the robot. Secondly, a spherical shell that encloses all sensors protects these from possible hazardous environments. For example, the shell stops any dust that deteriorates sensors or actuators when settling at sensitive locations. This is particularly useful for unknown and dangerous environments. E.g., for space applications, in the DAEDALUS study [8], a spherical robot is proposed that is to be lowered into a lunar cave and create a 3D map of the environment. The authors choose this format as the present moon regolith is known to damage instruments and other components.

This paper proposes to use such a spherical robot for mobile mapping man-made environments. In such environments, one advantage are architectural shapes following standard conventions arising from tradition or utility, i.e., there are many flat surfaces such as walls, floors, etc. that are sensed. Exploiting this fact yields more opportunities for registration as point-to-plane correspondences can be used. The proposed registration method minimizes the distances of each point to its corresponding plane as an objective function. The method is evaluated on a simulated dataset as well as on experimentally acquired datasets.

*To abide the FAIR-Principles of science, all data and code used to produce the results are given in this our repository (<https://github.com/fallow24/SphereTDP>).

2. State Of The Art

2.1. Spherical SLAM

While there exist camera-based approaches [9], to the best of our knowledge, SLAM with spherical robots and laser scanners was not done before. However, laser-based SLAM algorithms for motions in six degrees of freedom₁₁₀ (DoF) have been thoroughly studied. For outdoor environments [10] provides a first baseline. Adding a heuristic for closed-loop detection and a global relaxation Borrmann et al. yield highly precise maps of the scanned environment [11]. Zhang et al. propose a real-time solution to the₁₁₅ SLAM problem in [12]. They achieve the performance at a lower computational load by dividing the SLAM algorithm into two different algorithms: one performing odometry at a high frequency but low fidelity and another running at a lower frequency performing fine matching and registration₁₂₀ of the point clouds. More recently Dröschel et al. also propose an online method using a novel combination of a hierarchical graph structure with local multi-resolution maps to overcome problems due to sparse scans [13].

Since these approaches are based on point-to-point correspondences, they require a rather high point density to achieve precise registration. For low-cost LiDARs, this₁₂₅ implies slow motion and long integration time. Further, none of the approaches exploit the structure inherent to human-made environments, hence missing out on possible advantages.

2.2. Point Cloud Registration Using Plane Based Correspondences

The de-facto standard for many SLAM algorithms is the Iterative-Closest-Point (ICP) algorithm [14] that employs point-to-point correspondences using closest points,₁₃₅ as the name suggests. To overcome the requirements on point-density imposed by the point-to-point correspondences instead other correspondences are used. In human-made environments, planes are abundantly available and hence provide an attractive base for correspondences.

Pathak et al. [15] propose to reduce the complexity of the registration by using correspondences between planar patches instead of points. They demonstrate the effectiveness of their approach even with noisy data in cluttered environments. However, their approach is designed for data acquired in stop-scan-go fashion and not for mobile mapping applications. As they use a region growing procedure with randomized initialization for detecting planar patches the distortions in the data introduced by pose uncertainties are likely to effect the shape of the planar patches and lead to faulty correspondences.

Förster et al. use the planarity of human-made environment successfully in [16]. They register point clouds using plane-to-plane correspondences and include uncertainty measures for the detected planes and the estimated motion. Thereby, they propose a costly exact algorithm and cheaper approximations that yield high-quality maps.₁₄₅ Favre et al. [17] use point-to-plane correspondences after

preprocessing the point clouds using plane-to-plane correspondences to register two scans with each other successfully.

Both approaches use plane-to-plane correspondences to pre-register the scans. However, for pre-registration the classical point-to-point registration is also very effective. One advantage that point-to-point correspondences have over plane-to-plane correspondences is that they do not require a long stop in each pose. For plane-to-plane correspondences, this is necessary to gather enough data to measure planes in each scan robustly. The resulting scan procedure is stop-scan-and-go. In particular, for the application of a spherical robot this standstill in each pose cannot be guaranteed or even approximated, making continuous-time approaches using point-to-plane correspondences the method of choice.

In the following, we propose this combination of point-to-point based pre-registration followed by a point-to-plane based optimization.

3. Registration Algorithm

We start with transforming each line scan into the project coordinate system, which is defined by the pose of the first acquired line scan. With line scan, we mean the smallest chunk of range data we obtain from the scanner device driver. In the case of a SICK LMS1xx it is a line, and in case of a Livox scanner it has a flower shape. More details are provided in the following sections. For map improvement, the individual scans need to be registered to another. We propose an algorithm that consists of multiple steps outlined in algorithm 1. Based on ideas described in [18] we first rigidly register the scans and then further improve the overall map by exploiting the fact that human-made environments often consist of planes. We then find the planes in the pre-registered point cloud and then optimize the poses associated with the scans to minimize the distance of all points to their respective planes.

Algorithm 1: Registration algorithm for man-made environments

Result: A corrected map

1. Rigidly register the scans;
 2. Extract planes from the registered map;
 3. Further improve map by solving the optimization that minimizes the distance of all points to their respective planes;
-

3.1. Plane Extraction

After having done the rigid registration, the scans are aligned well enough to make statements about the potential planes in the environment. To find the planes in the environment, a Hough transform with an accumulator ball as described in [19] is used. In the next subsection, the

Hesse-normal form of the plane is required. For an ideal plane the distance parameter $\rho_{\mathcal{P}_i}$ is computed via $\mathbf{n}_{\mathcal{P}_i} \cdot \mathbf{x}_i$, where \mathbf{x}_i is an arbitrary point on the plane. To find this point, we first define a convex hull that encloses the plane. It is defined by the points that lie on the plane with the furthest distance to one another. We then choose the center point of the convex hull of the plane as \mathbf{x}_i .

3.2. Point-to-Plane Correspondences

There are many ways of finding correspondences between points and planes. However, even with the result not being perfect, we assume already globally registered scans, which is why a simple algorithm is sufficient: For each plane, consider adding a correspondence for all points closer to the plane than a threshold ϵ . Depending on the threshold value, some points now have multiple correspondences if their distance to multiple planes is less than ϵ . We then omit all points with correspondences to multiple planes from the optimization to avoid introducing errors due to the plane ambiguity.

3.3. Optimization

Assuming we now know the Hesse-normal form of all planes and all assigned points to these planes, we register the points to have a minimal distance to their respective planes. The transformation $T(\mathbf{p}_k)$ of each point \mathbf{p}_k with respect to a 6 DoF motion is described in homogeneous coordinates using the roll-pitch-yaw ($\varphi - \vartheta - \psi$) Tait-Bryan angles as in [20]. Transforming the result back from homogeneous coordinates and using C_k and S_k to denote the cosine and sine of the angle in the subscript yields:

$$T(\mathbf{p}_k) = \begin{bmatrix} xC_\vartheta C_\psi - yC_\varphi S_\psi + zS_\vartheta + t_x \\ x(C_\varphi S_\psi + C_\psi S_\varphi S_\vartheta) + y(C_\varphi C_\psi - S_\varphi S_\vartheta S_\psi) - zC_\vartheta S_\varphi + t_y \\ x(S_\varphi S_\psi - C_\varphi C_\psi S_\vartheta) + y(C_\psi S_\varphi + C_\varphi S_\vartheta S_\psi) + zC_\varphi C_\vartheta + t_z \end{bmatrix} \quad (1)$$

From this we define the function $D(\varphi, \vartheta, \psi, t_x, t_y, t_z, \mathbf{p}_k)$ that computes the distance of a point \mathbf{p}_k to its corresponding plane \mathcal{P}_i . Omitting the arguments of the function for simplicity:

$$\begin{aligned} D &= T(\mathbf{p}_k) \cdot \mathbf{n}_{\mathcal{P}_i} \\ &= n_{\mathcal{P}_i}^x (xC_\vartheta C_\psi - yC_\varphi S_\psi + zS_\vartheta + t_x) \\ &\quad + n_{\mathcal{P}_i}^y (x(C_\varphi S_\psi + C_\psi S_\varphi S_\vartheta) \\ &\quad \quad + y(C_\varphi C_\psi - S_\varphi S_\vartheta S_\psi) - zC_\vartheta S_\varphi + t_y) \\ &\quad + n_{\mathcal{P}_i}^z (x(S_\varphi S_\psi - C_\varphi C_\psi S_\vartheta) \\ &\quad \quad + y(C_\psi S_\varphi + C_\varphi S_\vartheta S_\psi) + zC_\varphi C_\vartheta + t_z) \\ &\quad - \rho_{\mathcal{P}_i} \end{aligned} \quad (2)$$

This distance function is what we want to minimize for all points and their respective planes. Hence the error function E is chosen as follows:

$$E = \sum_{\forall \mathcal{P}_i} \sum_{\mathbf{p}_k \in \mathcal{P}_i} \|D(\varphi, \vartheta, \psi, t_x, t_y, t_z, \mathbf{p}_k)\|_2^2 \quad (3)$$

Its gradient follows then immediately:

$$\nabla E = \sum_{\forall \mathcal{P}_i} \sum_{\mathbf{p}_k \in \mathcal{P}_i} \left[\frac{\partial}{\partial \varphi} E \quad \frac{\partial}{\partial \vartheta} E \quad \frac{\partial}{\partial \psi} E \quad \frac{\partial}{\partial t_x} E \quad \frac{\partial}{\partial t_y} E \quad \frac{\partial}{\partial t_z} E \right]^T \quad (4)$$

$$\Rightarrow \nabla E = \sum_{\forall \mathcal{P}_i} \sum_{\mathbf{p}_k \in \mathcal{P}_i} 2D(\mathbf{p}_k) [\nabla E_\varphi \quad \nabla E_\vartheta \quad \nabla E_\psi \quad n_{\mathcal{P}_i}^x \quad n_{\mathcal{P}_i}^y \quad n_{\mathcal{P}_i}^z]^T \quad (5)$$

Where

$$\begin{aligned} \nabla E_\varphi &= n_{\mathcal{P}_i}^x \quad yS_\varphi S_\psi \\ &\quad + n_{\mathcal{P}_i}^y (x[-S_\varphi S_\psi + C_\varphi C_\psi S_\vartheta] \\ &\quad \quad + y[-S_\varphi C_\psi - C_\varphi S_\vartheta S_\psi] \\ &\quad \quad - zC_\varphi C_\vartheta) \\ &\quad + n_{\mathcal{P}_i}^z (x[C_\varphi S_\psi + C_\varphi C_\psi S_\vartheta] \\ &\quad \quad + y[C_\varphi C_\psi - S_\varphi S_\vartheta S_\psi] \\ &\quad \quad - zS_\varphi C_\vartheta) \end{aligned} \quad (6)$$

$$\begin{aligned} \nabla E_\vartheta &= n_{\mathcal{P}_i}^x (-xS_\vartheta C_\psi + zC_\vartheta) \\ &\quad + n_{\mathcal{P}_i}^y (xC_\psi S_\varphi C_\vartheta - yS_\varphi C_\vartheta S_\psi + zS_\vartheta S_\varphi) \\ &\quad + n_{\mathcal{P}_i}^z (-xC_\varphi C_\psi C_\vartheta + yC_\varphi C_\vartheta S_\psi - zC_\varphi S_\vartheta) \end{aligned} \quad (7)$$

$$\begin{aligned} \nabla E_\psi &= n_{\mathcal{P}_i}^x \quad (-xC_\vartheta S_\psi - yC_\varphi C_\psi) \\ &\quad + n_{\mathcal{P}_i}^y (x[C_\varphi C_\psi - S_\varphi S_\vartheta S_\psi] \\ &\quad \quad + y[-C_\varphi S_\psi - S_\varphi S_\theta C_\psi]) \\ &\quad + n_{\mathcal{P}_i}^z (x[S_\varphi C_\psi + C_\varphi S_\psi S_\theta] \\ &\quad \quad + y[-S_\psi S_\varphi + C_\varphi S_\vartheta C_\psi]) \end{aligned} \quad (8)$$

and $\mathbf{\Pi} = [\varphi \quad \vartheta \quad \psi \quad t_x \quad t_y \quad t_z]^T$.

As the gradient is well-defined we minimize the error function with any gradient based method. The commonly used, well-known stochastic gradient descent (SGD) algorithm computes

$$\mathbf{\Pi}_{k+1} = \mathbf{\Pi}_k - \alpha \nabla E \quad (9)$$

To accelerate convergence and to improve the found solution further modifications are made.

Since we have vastly different effects on the error function by each dimension, the first consideration for improving the SGD is the following: Typically, changes in orientation, i.e., the first three elements of the gradient vector $\frac{\partial}{\partial \varphi} E$, $\frac{\partial}{\partial \vartheta} E$, and $\frac{\partial}{\partial \psi} E$, have much more impact on the error function than a change in position. This is intuitively explained since translating the scan makes the error grow linearly for all points. However, when rotating the scan, points with a larger distance to the robot are moved drastically, leading to a higher sensibility on the error function. For this reason, the α applied on orientation has to be much smaller than the α applied on the position. It becomes obvious that α needs to be extended into vector form, $\boldsymbol{\alpha}$, therefore weighting each dimension differently.

Another consideration to speed up SGD is to adaptively recalculate $\boldsymbol{\alpha}$ for each iteration. We employ and modify ADADELTA as a technique to do so, which is described in detail in [21]. The main idea is the following: It extends the SGD algorithm by two terms. First, an

exponentially decaying average of past gradients, which is¹⁸⁰ recursively defined as

$$\mathbf{G}_{k+1} = \rho \mathbf{G}_k + (1 - \rho) \nabla E^2 \quad (10)$$

and second, an exponentially decaying average of past¹⁹⁵ changes, which is defined as

$$\mathbf{X}_{k+1} = \rho \mathbf{X}_k + (1 - \rho) \alpha \nabla E^2 \quad (11)$$

where $\rho \leq 1$ is a decay constant, typically close to 1. The root mean squared (RMS) of these quantities are²¹⁰

$$RMS[\mathbf{G}]_k = \sqrt{\mathbf{G}_k + \epsilon} \quad (12)$$

and

$$RMS[\mathbf{X}]_k = \sqrt{\mathbf{X}_k + \epsilon} \quad (13)$$

where $\epsilon > 0$ is a very small constant, typically close to 0. It will prevent dividing by zero in the recalculation of α , which is as follows:

$$\alpha_k = \frac{RMS[X]_{k-1}}{RMS[G]_k} \quad (14)$$

For our particular application, ADADELTA behaves a little too aggressively. Despite giving a good measure on how to adapt α , the algorithm sometimes overshoots, and convergence doesn't happen. Therefore, we employ another scaling factor, typically not found in ADADELTA,²²⁵ extending eq. (14) to:

$$\alpha_k = \alpha_0 \cdot \frac{RMS[X]_{k-1}}{RMS[G]_k} \quad (15)$$

where α_0 holds the scaling factors for each dimension.²³⁰

Finally, the SDG model is improved using eq. (15) and extends to

$$\Pi_{k+1} = \Pi_k - \alpha_0 \frac{RMS[X]_{k-1}}{RMS[G]_k} \cdot \nabla E \quad (16)$$

Using this algorithm once after finding correspondences from points to planes leads to convergence to a local minimum, which often isn't an optimal solution. Even if we increase the number of iterations dramatically, no better solution than the local minimum is found. That is unless you consider updating the correspondence model after i ¹⁸⁵ iterations of gradient descent. Re-assigning point-to-plane correspondences this way k times, and if k is chosen large enough, it leads to an optimal solution after maximum $n = k \cdot i$ iterations of gradient descent.

3.4. Further Optimizations of the Algorithm

The algorithm was extended by two further optimizations, which are helpful in different scenarios.

Firstly, we introduce a lock on some dimensions from being optimized by setting the corresponding α_i to zero.²⁴⁰ Although 6D optimization generally works, reducing the

optimization space is particularly useful if the source of error in the system is known and a model exists. That way, e.g., a point cloud from a terrestrial laserscanner that experiences irregularities in its spinning mirror is registered by optimizing only over the axis of rotation as no other movement is to be expected.

Secondly, we employ a continuous iteration, where the scans are processed sequentially. This is especially useful for mobile systems, where pose error accumulates due to increasing tracking uncertainties. The assumption is that the error in one scan is also present in the following scan, plus some unknown new error. We eliminate the error from scan m which is also present in scan $m+1$ by applying the pose change from scan m , $\Pi_{n,m} - \Pi_{0,m}$ after n gradient descent iterations, to scan $m+1$, before restarting gradient descent. To quantify the quality of the proposed registration method, it is tested on simulated and real-world data.

4. Simulation

For the simulated data, we implemented a noisy world-robot-sensor model. We are simulating a Livox-Mid100 [22] laser scanner with customizable noise level on the range measurements inside a robot with different motion capabilities, subject to noise in its pose estimation. This yields scan results similar to the ones obtained in the real world.

4.1. Simulated Sensor

The Livox-Mid100 laser scanner consists of three smaller-sized Mid40 scanners arranged to provide an overall field-of-view of 98.4° (Horizontal) by 38.4° (Vertical). It provides a range precision of 2 cm up to 20 m range and yields 300.000 points/s. A particular advantage of the Livox laser scanners is their unique scanning pattern. The scanners use two motorized, so-called Risley prisms to steer the beam deflectance. For the specific ratio of rotation speeds used in the Livox scanners, the beam traces out a non-repetitive, flower-shaped scanning pattern [23]. Since the pattern is non-repetitive, the point density increases with integration time, enabling denser measurements.

4.2. Range Noise Model

Most real laser scanners are subjected to range measurement noise that is proportional to the measured range. Therefore the simulated sensors are as well. To achieve this, we sample a noise percentage n_P from some normal distribution $\mathcal{N}(\mu, \sigma^2)$. The resulting range r given the true range r_t is then

$$r = r_t(1 + n_P) \quad (17)$$

For each measurement ray the noise percentage is sampled independently.

4.3. Pose Estimation Noise Model

For the pose measurement, one cannot simply add white noise to the current pose estimate as this does not capture the integration error, which is common among inertial measurement units (IMU). Therefore we assume a disturbance torque about the two axes that lie in the ground plane. This is equivalent to a case where a slightly shifted ground plane or an unbalanced locomotion system of the robot is present.

Accordingly, a spherical robot that is assumed to be translating exactly along one axis by rotation exactly about one other axis at an angular velocity ω experiences random disturbance torques at each time instant that accelerate the sphere's rotation about the respective axes. This additional motion is determined by integrating the disturbance torques, which are sampled from some normal distribution $n_\phi, n_\psi \in \mathcal{N}(\mu, \sigma^2)$ each. The pose update in the discrete simulation is therefore given by:

$$\begin{bmatrix} \varphi \\ \vartheta \\ \psi \\ x \\ y \\ z \end{bmatrix}_{k+1} = \begin{bmatrix} \varphi \\ \vartheta \\ \psi \\ x \\ y \\ z \end{bmatrix}_k + \begin{bmatrix} 1 \\ 0 \\ 0 \\ R \\ 0 \\ 0 \end{bmatrix} \omega \Delta t + \Delta t \sum_{i=0}^k \underbrace{\begin{bmatrix} n_\varphi[i] \Delta t \\ 0 \\ 0 \\ n_\psi[i] \Delta t \\ 0 \\ 0 \end{bmatrix}}_{\text{Difference in angular velocity}} \quad (18)_{295}$$

Assuming intended locomotion along the z -axis and unintended locomotion along the x -axis where R is the sphere radius. No movement upwards is possible since the robot moves on a flat ground, hence the entry is zero.

4.4. Simulated Datasets

Figure 1 shows a noise-free trajectory through a simulated environment and a trajectory with noisy sensors while figure 2 shows a rendering of the simulated robot as well as the simulation sequence. In the noise-free case, the trajectory slightly bends in the direction of disturbance torque sideways while also varying in velocity in the intended direction of travel. In the noisy case, the ideal straight trajectory is assumed. Hence the planes enclosing the room are sensed multiple times. In particular, we see that the trajectory of the robot leads through one of the sensed planes. Also, the further the sensed points are, the noisier they appear, which is consistent with the larger influence of the pose error at higher distances.

5. Experimental Setup

We also tested our algorithm on a real-world dataset that adheres to different motion profiles and laser scanners type with different scanning patterns than the simulated data.

The dataset is collected by a line scanner, in particular a SICK LMS141 industrial scanner, inside a sphere of a diameter of 20 cm that lies on a floating desk, which is

air-pressurized, such that the sphere is hovering. On this floating desk, the sphere can rotate freely about all axis while being fixed in position. Hence, in this experiment the optimization space can be reduced to a rotation. Further, without the motion, the 2D laser cannot obtain a 3D model from the environment, thus requiring registration. The sphere is equipped with a low-cost IMU, i.e., a PhidgetSpatial Precision 3/3/3, to estimate the orientation, a battery pack and a raspberry pie for processing.

Figure 3 shows the experimental setup. The left column of figure 5 shows the pre-registered resulting point cloud. We see that the point cloud is rather noisy, and in particular, the walls are sensed multiple times, hence appearing very blurry.

6. Results

6.1. Simulated Results

The plane-based registration is applied to the simulated dataset with noisy pose and range measurements (cf. Figure 1) without further processing. Assuming this represents a coarsely pre-registered 3D point cloud, the distances to the ground truth were evaluated before and after the plane-based registration. Figure 4 shows the different point-to-point distances.

Before the registration, the corridor is only represented acceptably in the front part. The further into the corridor, i.e., the longer the robot accumulates error, the more imprecise the data becomes. Finally, we see that a large portion of the data even exceeds either the 1 m error, contributing to the large spike in the histogram or even the 2 m error limit; thus, being cut from the representation. After registration, we see that, qualitatively, the ideal corridor was nearly restored from the noisy data. In particular a very large portion (95%) have less than 17 cm distances. Further, the square and straight shape of the corridor is restored well, and especially the large spike at errors of greater than 1 m is removed. Any such errors tend to occur at the back and the front of the corridor where the measured range is the largest hence has the largest contribution of the range error.

6.2. Floating Sphere Results

Figure 5 shows the results obtained before and after employing the plane base registration on the dataset acquired by the floating sphere. We combine ten scans into one meta-scan, which is then globally registered. This does not only speed up convergence due to the proportional effect on the error function but also decreases the risk of transforming the scan in a senseless way. Transformations like these happen when incorrectly labeled points have a huge effect on the error gradient, which is especially the case when considering only a few points.

After the registration, the walls of the room are significantly more prominent in the point cloud. In particular,

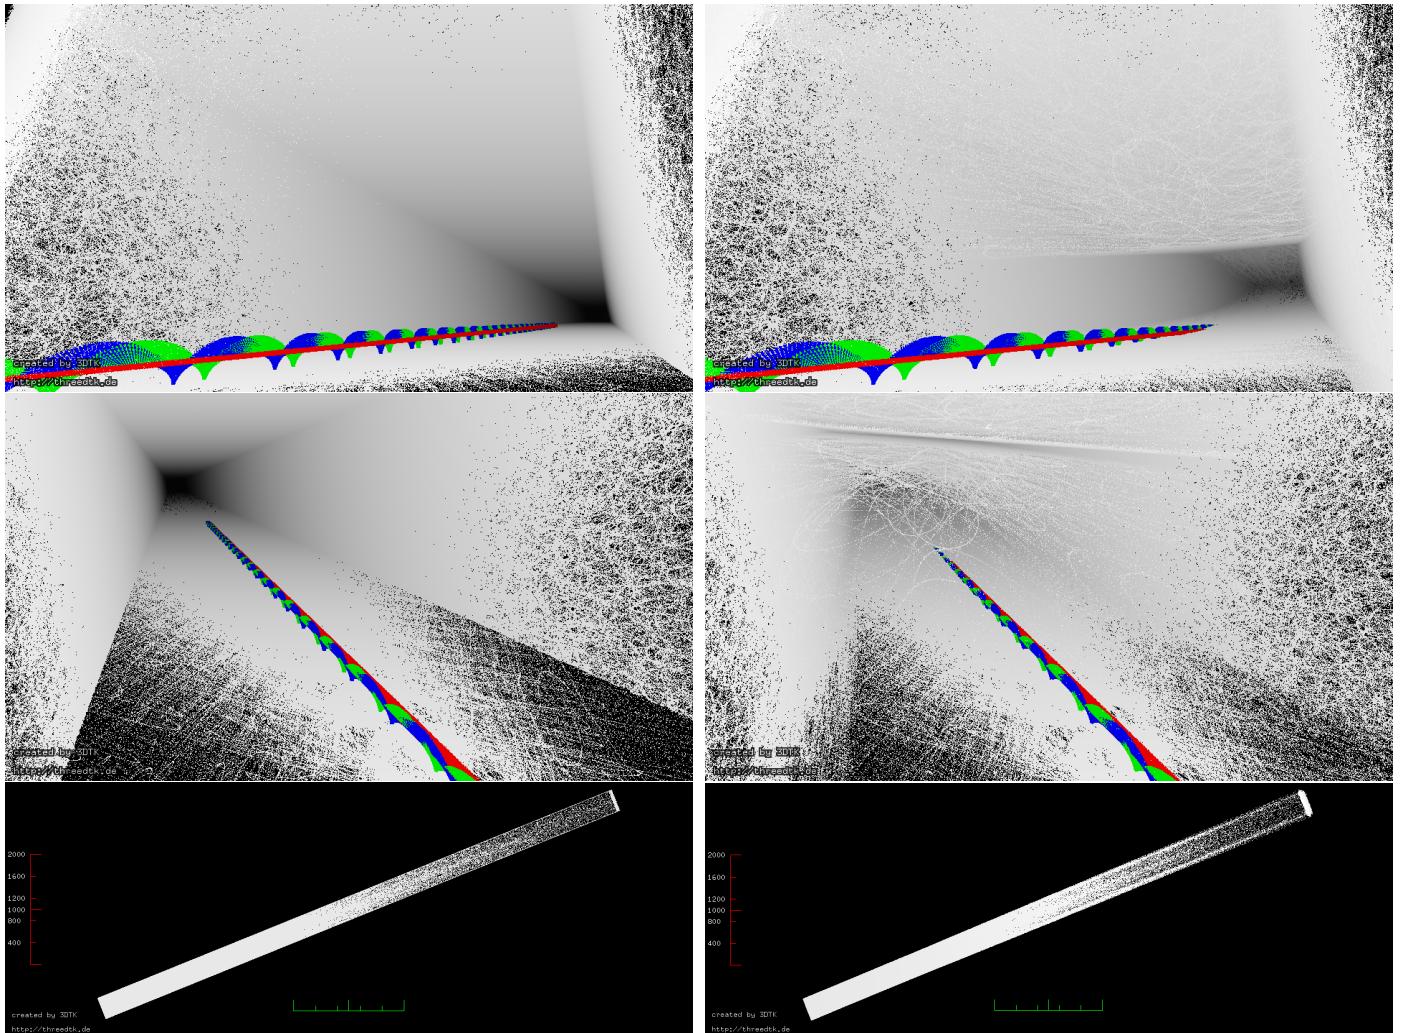

Figure 1: Two simulated datasets of a long hallway of size $4 \text{ m} \times 3 \text{ m} \times 100 \text{ m}$. Ideal noise free (left), noisy pose ($\mathcal{N}_\varphi = \mathcal{N}_\psi(\mu = 0.0001, \sigma = 0.00001)$) and noisy range measurements ($\mathcal{N}_r(\mu = 0, \sigma = 0.001)$) (right).

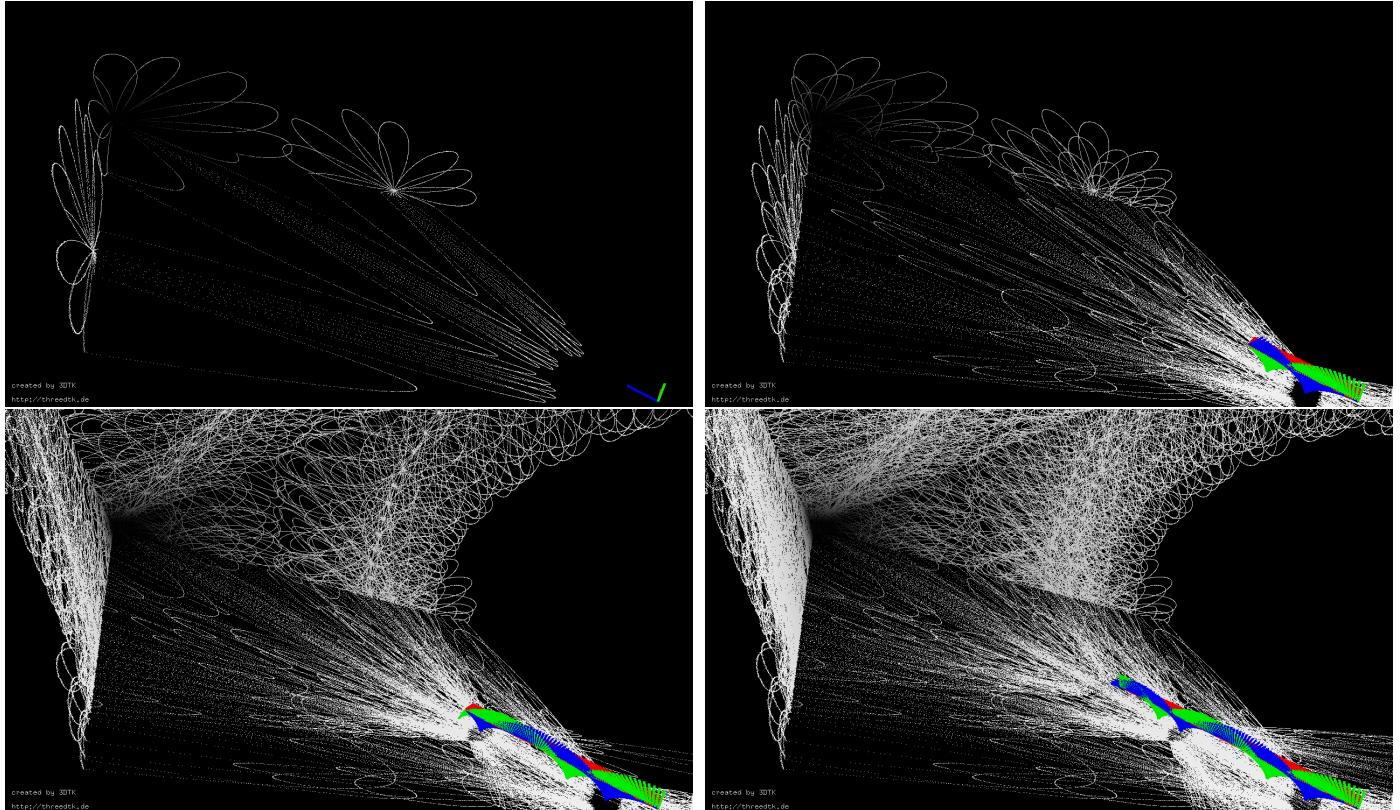

Figure 2: Top: Initial sequence of the simulation of the ideal dataset showing the simulated motion of the robot. Below: Rendering of the simulated robot, a Livox laser scanner inside a spherical shell.

Figure 3: Data acquisition using floating sphere. Top: A sequence of orientations the sphere assumes during data acquisition. Bottom: Hardware setup of the sphere.

the noise in the top left corner of the top view (cf. figure 5) has been visibly reduced. Further, the deviation of points around the walls is notably smaller as the points are moved on the plane.

However, some imprecisions remain. In particular, at the initially very noisy top left corner of the top view, a few points cannot be matched to the plane. The scans that cause these imprecisions are problematic as they measure a number of plane-like structures in the interior of the room. When relabeling those scans, the interior points are associated with a plane, and hence the corresponding distance is minimized.

7. Conclusion

In this paper, we have proposed a registration method for man made environments that exploits the structure of those environments. Given that in human-made environments parallel planes and right angles are abundantly available, we employ point-to-plane correspondences to improve a pre-registered 3D point cloud. We have evaluated the procedure on a simulated dataset and on an experimentally acquired dataset with different motion profiles. In this evaluation, we have shown that the procedure improves both datasets and yields more human-made, structure-like maps. In particular, the qualitative structure of the environments is reconstructed well. In the resulting maps, the parallel walls are clearly improved.

However, as section 5 shows, some outliers remain due to the simplistic point-to-plane correspondence model, which is to be improved in future studies. One idea to do so is to employ a local clustering technique onto the individual scans before registering them globally. Points from the scan with a similar normal get clustered together if their distance is small enough. This way, a cluster represents a local plane while at the same time storing all the points that belong to that plane. Point-to-plane correspondences then arise from the intersection of local clusters with global planes.

Needless to say, a lot of work remains to be done. Right now, not all steps in the procedure are autonomous, in particular the parameter tuning. In the future, one goal is to increase the autonomy of the system. One approach is to introduce soft-locks for the optimization dimensions. I.e., instead of locking some dimensions entirely from being used for optimization, they are weighted based on the dynamics of the system that encode which noise source is more likely. Currently, we are assembling the sphere of Figure 2 to test it in real environments. Unfortunately, this sphere will be too large to fit our floating setup, thus it will be tested in an office like environment. Furthermore, we will test our rolling and scanning spheres on a rail system to achieve repeatable trajectories.

Acknowledgement

The authors thank the Cylon team (Ignacio Dorado Llamas, Timothy Randolph, Camilo Andres Reyes Mantilla) for designing and building the prototype and Timo Burger for acquiring the floating table data set. Special thanks to Dieter Ziegler and Sergio Montenegro for supporting our work. We acknowledge funding from the ESA Contract No. 4000130925/20/NL/GLC for the “DAEDALUS – Descent And Exploration in Deep Autonomy of Lava Underground Structures” Open Space Innovation Platform (OSIP) lunar caves-system study and the Elite Network Bavaria (ENB) for providing funds for the academic program “Satellite Technology”.

A maximal distance of 2 m is set, such that all points that display a higher distance value are excluded from the analysis. Further, the histogram joins all values with a distance greater than 1 m into the last bucket. The top two columns show a heat map of distances, while the bottom shows the corresponding histogram. The color mapping is equivalent in both. An animation of the matching process is given at <https://youtu.be/0ps5Pg4qo4E>.

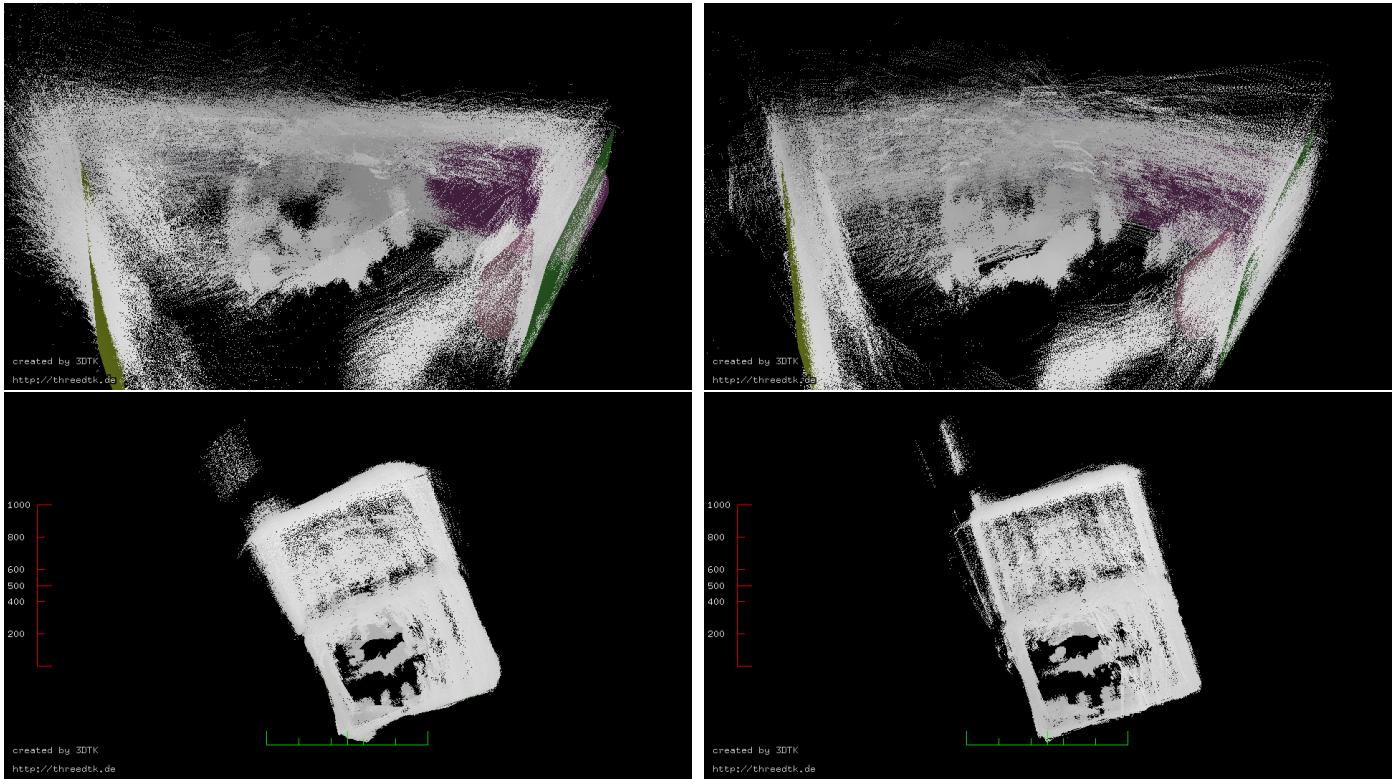

Figure 5: The point cloud acquired by the floating sphere before (left) and after (right) applying the plane based registration. View from the interior that shows the used planes (top) and a birds-eye view (bottom). An animation of the registration process is given at https://youtu.be/8XdIUN_9VpY.
